Dedication

I am extremely grateful to my supervisor, Jim Connelly, whose guidance, patience, wealth of knowledge, optimistic outlook, extraordinary teaching and friendship have been a constant source of inspiration. Thanks to committee member Sharon Mosher for helpful discussions, a great experience in Structural Petrology and for valuable comments during editing. Thanks also to my other committee member, Leon Long, for introducing me to isotopes and for painstakingly thorough editing. This thesis benefited greatly from the scientific input and logistical help of Karl-Inge Åhäll, University of Göteborg, Sweden. Our discussions always proved stimulating. Tack! Kathy Manser, what would I have done without you? Your time, patience and assistance through every step of the analytical work is so appreciated, not to mention the laughter and friendship (and food). Thank you, Benjamin Purcell, for your brains and brawn during the seven weeks in Sweden and for so much more. Laurie Schanz, you have been here for it all! Thank you for your tremendous editing, your friendship and especially for all that fuel! To Sven Larsson of Wästana, your generosity is unsurpassed, and I smile every time I think of you. Thanks to Dennis Trombatore for being the greatest librarian ever. Thanks also to Greg Thompson for thin sections and to Lu Xianfeng for help on the probe and the SEM. I appreciate computer and graphics support from Kurt Bartelmehs and Jeffrey Horowitz.

I appreciate computer and graphics support from Kurt Bartelmehs and Jeffrey Horowitz.

Discussions with Steve Grimes, Dave Hirsch, Rob Reed, Alex Riter and Jim Rougvie are truly appreciated. Thanks to the Department of Geological Sciences for providing five semesters and two summers of T.A. support and to the Department and to Laura and Thomas Barrow for two semesters of fellowship support. Thanks to Dr. Jim Connelly for R.A. support during summer 1996, funded by NSF Grant EAR-9418236. Thanks also to Conoco for scholarship support during my last semester. The field component of this research was made possible by grant support from the Geological Society of America, Sigma Xi, The University of Texas at Austin Geology Foundation and the Swedish Geological Survey. And to Mom and Dad, Granny, Martin and Maureen: your love, encouragement and interest in everything I do means the world to me.

Supervisor: James N. Connelly

The Åtran terrane of southwestern Sweden is a Mesoproterozoic, polydeformed terrane and a product of crustal growth westward away from an Archean core. Both Gothian (Labradorian) and Sveconorwegian (Grenvillian) deformations are recorded, but it is difficult to identify the effects of each deformation because the resultant fabrics are essentially parallel. Recent debate regarding the timing of regional gneiss-formation revolves around two distinct hypotheses; one assigns the bulk of the deformation to the Gothian Orogeny and the other attributes it to the Sveconorwegian Orogeny.

Submitted to the Committee November, 1997

Abstract

Mesoproterozoic tectonothermal development of southwestern Sweden: New age constraints using field relationships and U-Pb geochronology

Catherine Anne Christoffel, MSGeoSci

The University of Texas at Austin, 1997

Supervisor: James N. Connelly

The Ätran terrane of southwestern Sweden is a Mesoproterozoic, polydeformed terrane and a product of crustal growth westward away from an Archean core. Both Gothian (Labradorian) and Sveconorwegian (Grenvillian) deformations are recorded, but it is difficult to identify the effects of each deformation because the resultant fabrics are essentially parallel. Recent debate regarding the timing of regional gneiss-formation revolves around two distinct hypotheses; one assigns the bulk of the deformation to the Gothian Orogeny and the other attributes it to the Sveconorwegian Orogeny.

U-Pb ages from four lithotectonic units constrain the timing of tectonic and thermal events for the region. Primary, igneous zircons from a felsic orthogneiss yield a protolith crystallization age of 1664 ± 7 Ma. The first dyke suite intruded the gneisses immediately after the earliest deformation and was then metamorphosed at 1654 ± 9 Ma during the second major deformation and migmatization event. Migmatitic layers in the gneisses and mafic dykes are cross-cut by less deformed dykes of the second dyke suite that crystallized between 1426 ± 9 Ma and 1399 ± 7 Ma. The Gothian Orogeny was thus responsible for the majority of the deformation and migmatization recorded in the study area. In addition to *ca.* 1.4 Ga magmatism, metamorphism at 1438 ± 12 Ma resulted in new zircon growth in the mafic gneiss. This magmatism and metamorphism are interpreted to be a local manifestation of a regional inter-orogenic thermal event that may be related to *ca.* 1.4 Ga magmatism known elsewhere in southwestern Sweden. Sveconorwegian deformation, constrained by the undeformed third dyke suite, occurred before 946 ± 6 Ma. Metamorphic (re)crystallization of monazite (948 ± 9 Ma), titanite (932 ± 5 Ma and 935 ± 7 Ma) and rutile (878 ± 9 Ma) indicate late-Sveconorwegian static metamorphism and suggest slow cooling rates of 4.5 – $11^\circ\text{C}/\text{million years}$ from 948 Ma to 932 Ma and 2.5° – $5^\circ\text{C}/\text{million years}$ from 932 Ma to 878 Ma during erosion and collapse of the Sveconorwegian Orogen.

Chapter 1 Introduction

Prologue

This thesis is divided into two chapters. Chapter 1 introduces the study, discusses project logistics and provides detailed descriptions of lithologic units in the study area and their relative structural relationships. The lithologic descriptions provide detail of mineralogical and structural aspects of the units, both macroscopic and microscopic, and may be useful for future studies of a similar nature in southwestern Sweden. Chapter 2 is a paper on the tectonothermal evolution of southwestern Sweden to be submitted to *Precambrian Research* for publication. Some material presented in Chapter 1 may be repeated in Chapter 2 because the latter is meant to stand alone.

tectonic and thermal events between Baltica and Laurentia.

The field area for this study is located in southwestern Sweden between Falkenberg and Halmstad (Figures 1.1 & 1.2). It was chosen for its excellent exposure and presence of structural fabrics that are similar to those of other areas in the same tectonic terrane. At least two Mesoproterozoic orogenic events affected the area; thus, accurate tectonothermal models require the correct separation of deformational and metamorphic effects into their respective orogenic events.

Discrepancies exist regarding the timing of regional gneiss-formation of the orthogneisses of southwestern Sweden (Åhäll, 1996; Connolly & Åhäll, 1996; Connolly et al., 1996; Johansson et al., 1996; Åhäll et al., 1997b; Möller &

Chapter 1: Introduction

The Grenville Orogen of North America spans the southern and eastern margins of Laurentia from Mexico, through Texas to eastern Labrador, Canada, and has been correlated across the present-day Atlantic Ocean into Scandinavia (Gower, 1990) where it is referred to as the Sveconorwegian Orogen. The relationship between these two orogenic belts is complicated because formerly interposed crustal material is now missing. Detailed studies of the Sveconorwegian Orogen that incorporate field and structural geology with reliable radiometric ages are essential to develop a better understanding of the tectonic evolution of the Baltic craton. They also facilitate correlations of tectonic and thermal events between Baltica and Laurentia.

The field area for this study is located in southwestern Sweden between Falkenberg and Halmstad (Figures 1.1 & 1.2). It was chosen for its excellent exposure and presence of structural fabrics that are similar to those of other areas in the same tectonic terrane. At least two Mesoproterozoic orogenic events affected the area; thus, accurate tectonothermal models require the correct separation of deformational and metamorphic effects into their respective orogenic events.

Discrepancies exist regarding the timing of regional gneiss-formation of the orthogneisses of southwestern Sweden (Åhäll, 1996; Connelly & Åhäll, 1996; Connelly et al., 1996; Johansson et al., 1996; Åhäll et al., 1997b; Möller &

Söderlund, 1997). New field and U-Pb data presented here address this discrepancy and contribute to a better understanding of the regional geology, including the relative and absolute timing of thermal and deformational events for the southern margin of Baltica during the Mesoproterozoic. These data are also useful for refining tectonic models for southwestern Sweden and for correlation between continents.

PROJECT LOGISTICS

Field work was conducted during the summer of 1995. A party of two spent seven weeks mapping detailed field relationships and collecting samples for isotopic and petrographic analyses. The mild terrain of the study area consists of excellent exposure along the coast and in inland quarries. Elsewhere in the study area, vegetation covers the bedrock. Wave-washed coastal exposures were especially good for examining structural and igneous intrusive relationships between different units to work out the relative timing of geologic events. The quarries, by their very nature, generally do not contain more than one lithology. Thus, they are less valuable in providing information about the timing of regional events, but nevertheless they are important for understanding the deformation and thermal history of the dominant units of the area. Sample processing and U-Pb isotopic analyses were performed at the University of Texas at Austin.

LITHOLOGIES AND STRUCTURAL RELATIONSHIPS

Four major rock units in the study area were examined to better understand their relative chronologic relationships, deformational histories and metamorphic evolution. Each unit is separated from the next youngest by one or more

deformation events (Table 1.1). Thus, the units were identified on the basis of penetrative D1-D5 deformation features. The region of interest predominantly comprises gneisses that were first deformed during D1 and were intruded by at least three generations of younger dykes (Figure 1.3). The earliest suite comprises mafic dykes that were deformed during D2. Felsic and mafic dykes of the second suite cross-cut D1 and D2 fabrics, and were deformed during D4. Felsic and mafic dykes of the third suite cross-cut all of the D1-D4 fabrics, and some show evidence of D5 deformation.

Gneiss Package

The oldest rocks in the area include interlayered felsic, intermediate and mafic orthogneisses and supracrustal gneisses. Contacts between the different orthogneisses are concordant and parallel to intra-formational S1/S2 gneissic layering. A well-developed S1/S2 composite foliation, closed to isoclinally folded (F3) foliations, L4 lineations and later, open F5 folds demonstrate the polydeformational history of the orthogneisses.

Felsic & Intermediate Orthogneisses

Felsic and intermediate orthogneisses comprise the dominant unit. The appearance of these rocks is consistent throughout the field area in both coastal and quarry exposures with the exception of the area near Skipås (Figure 1.2), discussed below. The foliation varies in intensity and is generally defined by compositional interlayers of granitic and mafic material and locally defined by weakly aligned biotite, hornblende, feldspar augen and quartz ribbons.

Table 1.1. Mesoproterozoic emplacement and deformation history in the Falkenberg-Halmstad area, southwestern Sweden. U-Pb ages from this study constrain the timing of events.

INTRUSION/ DEFORMATION (D)	ASSOCIATED FOLIATIONS (S)	ASSOCIATED FOLDS (F) & LINEATIONS (L)	AGE CONSTRAINTS
Orthogneisses (and Skipås granite)			1664±7 Ma
D1	S1 , defined by N1 leucosome	-	
1st Dyke Suite			
D2	N2 generated & flattened. N2 cross-cuts N1 . S2 parallel to S1 .	-	1654±9 Ma
D3	S3 , axial planar fabric to F3 folds. Some minerals of S1 & S2 realigned.	F3 , folds S1 & S2	timing unknown. Gothian or early "Hallandian."
2nd Dyke Suite			1426+9/-4 Ma 1399+7/-6 Ma
D4	S4	F4 folds C- dykes, L4	timing poorly constrained.
D5		F5 , gentle N-S trending	
3rd Dyke Suite (deformed)			
3rd Dyke Suite (undeformed)			946+6/-4 Ma

Two distinct leucosomes occur in these gneisses. The first generation (**N1**) consists of fine- to medium-grained, homogeneous, 0.5 to 2 cm thick, pink, gray and white layers that, in conjunction with the more mafic layers, define the **S1** gneissosity (Table 1.1). Younger, medium-grained to pegmatitic leucosomes (**N2**) (Figure 1.4) cross-cut **S1**. **N2** leucosomes commonly pinch out and range in thickness from 1 to 10 cm. They contain a fabric (**S2**) that is parallel to sub-parallel to the regional **S1** foliation, thus defining a composite foliation (**S1/S2**).

Figure 1.3. Schematic diagram of present-day field relationships, examined to constrain a relative chronology of events in the study area.

Figure 1.4. D1-D3 structural relationships between S1/S2, N1 and N2 in the felsic orthogneiss. F3 folds fold S1/S2 in the orthogneiss and S2 in the first dyke suite.

Closed to isoclinal F3 folds fold S1/S2, and minerals in N1 and N2 layers are realigned parallel to a weak to moderate S3, axial planar (F3) foliation. A third generation of leucosome (N3) is found locally (Figure 1.5).

The felsic gneiss exhibits a later, well-developed regional lineation (L4). L4 is not ubiquitous, and where present varies from moderate to strong. In N2 and N3 layers it is especially well developed, forming a coarse mineral lineation defined by elongate quartz and feldspar. A corresponding S4 foliation, apparent in younger units, parallels the S1/S2 foliation.

The felsic gneiss contains $qtz+pl+kfs\pm bt\pm hbl\pm ms\pm grt$ (Appendix A) with biotite and muscovite as either stable or retrograde phases. Muscovite locally displays mimetic growth on biotite. All samples contain accessory zircon, opaque minerals and apatite. Both euhedral and anhedral zircons are present, and many of the crystals contain cores (Figure 1.6). Several samples contain allanite. Twinned plagioclase grains commonly have exsolution lamellae and myrmekitic intergrowths. Chlorite and sericitized plagioclase are products of retrograde reactions.

Most occurrences of the felsic and intermediate gneisses show a highly recrystallized, sugary texture such that distinctive mineral fabrics are rare. Static recrystallization textures, such as straight and cusped grain boundaries and 120° triple junctions, dominate (Figure 1.7).

Skipås Granite

The Skipås granite, located near Skipås (Figure 1.2) is an approximately 3 km², homogeneous, very-fine- to coarse-grained, strongly lineated (L4), felsic

Figure 1.5. Mafic dyke from the first suite intruding the felsic orthogneiss. The dyke shows S2 compositional layering (inset) and boudinage. N2 fills interboudin spaces, and coarser-grained N3 lies along the dyke margin and in interboudin spaces. White box shows area of inset. Pocket knife is 9 cm long.

Figure 1.6. Photomicrograph of zircon in a felsic orthogneiss. A core is clearly seen within the zircon. Zircons with cores were carefully avoided for U-Pb geochronology. Field of view is 0.75 mm across.

Figure 1.7. Photomicrograph of statically recrystallized quartz and feldspar. This texture is common to all felsic units and indicative of continued metamorphism after Sveconorwegian deformation. Field of view is 3.3 mm across.

orthogneiss that escaped migmatization and much of the gneiss-forming deformation. The strong to very strong L4 lineation of this L-tectonite is defined by aligned elongate K-feldspar augen and quartz ribbons (Figure 1.8). The Skipås granite grades from unfoliated to weakly foliated, with pinch-and-swell contacts between foliated and unfoliated zones. Interlayered quartzo-feldspathic and mafic layers and aligned hornblende, biotite and elongate K-feldspar augen define a weak foliation. The foliation is parallel to the strong, regional S1/S2 foliation in the orthogneisses and is therefore correlated with S1/S2. The Skipås granite is host to dykes that have seen the effects of the regional D2 gneiss-forming event. Field relationships therefore suggest that the Skipås granite is at least as old as the surrounding felsic gneisses, yet its foliation is not nearly as well developed.

The mineral assemblage of the Skipås granite consists of $kfs+pl+qtz+hbl\pm bt\pm grt$ (Appendix A) plus subordinate apatite, opaque minerals and zircons with cores. Feldspar intergrowths and myrmekitic textures are common. Very small anhedral garnets and medium-grained poikiloblastic garnets with inclusions of opaques, plagioclase, hornblende and quartz are also common. Retrograde chloritization and sericitization affected the unit.

The Skipås granite is also strongly recrystallized, and static recrystallization textures dominate. Quartz and feldspar have 120° triple junctions and straight and cusped grain boundaries. Dynamic recrystallization textures indicate rotational recrystallization of quartz and feldspar and migrational recrystallization of quartz by grain boundary migration and bulge nucleation.

Figure 1.8. Photograph of the Skipås granite. Note the unit's strong linear fabric (L4) and lack of a planar fabric. D2 deformation affected the mafic rocks in the foreground. Rock hammer for scale.

Mafic Amphibolite and Mafic Granulite Orthogneisses

Mafic gneisses are interlayered with the felsic and intermediate gneisses and comprise the second most abundant rock type in the study area. Thicknesses of the mafic gneiss layers range from one meter to approximately 60 meters. All mafic gneisses are S-tectonites with the main gneissic fabric (S1/S2) defined by 0.5 to 10 cm thick compositional layers and less commonly by aligned minerals. Alternating layers of hbl+bt+grt±cpx and plagioclase-rich leucocratic layers define the compositional layering. Aligned hornblende and biotite crystals and elongate quartz ribbons define mineral fabrics. Foliation intensities range from weak to strong planar fabrics, and F3 isoclinally folded S1/S2 compositional layers are common. Some thin (~5 m thick) mafic gneiss layers are boudinaged.

N1 leucosomes vary in appearance from irregularly-shaped aggregates to extremely-flattened and isoclinally folded (F3) stringers (Figure 1.9). Spacing between individual leucosomes varies from tens of centimeters to only a few millimeters. Leucosomes are generally fine grained and contain abundant plagioclase, with lesser abundances of quartz, K-feldspar and garnet. N2 leucosomes occur locally, are coarse grained and are commonly found along the contact between the mafic and felsic gneisses.

Fine- to coarse-grained mafic gneisses have local variations in mineral assemblages, but generally comprise pl+hbl+bt+grt±cpx±qtz±scpx±ms (Appendix A). Accessory minerals include anhedral zircon, titanite, opaque minerals and apatite. The mafic gneiss at one locality contains orthopyroxene phenocrysts up to 3 cm in diameter, with retrograde corona textures comprising,

Figure 1.9. Recrystallized mafic orthogneiss, displaying the two end-member styles of leucosomes. The N2 leucosome at the bottom of the photograph is flattened and isoclinally folded, whereas the leucocratic material above and to the right of the pocket knife appears as irregularly shaped aggregates. Pocket knife is 9 cm long.

from core to rim, vermicular intergrowths of clinopyroxene and quartz rimmed by hornblende, quartz, garnet and plagioclase (Figure 1.10). Biotite and opaque minerals are locally present; the opaque minerals display a symplectic texture with clinopyroxene, hornblende and plagioclase (Figure 1.11).

Mineral textures indicate interaction between biotite and hornblende, clinopyroxene and opaque minerals, and clinopyroxene and plagioclase. Garnet with plagioclase coronas and biotite replaced by opaque minerals occur locally. Garnets, up to 7 cm in diameter, occur in several places, locally accompanied by quartz pressure shadows (Figure 1.12). Poikiloblastic garnets with inclusions of hornblende, biotite, plagioclase and zircon are common.

Biotite is found as both a stable, prograde phase and a retrograde phase, and some samples contain multiple generations of biotite. Only samples from Gåsanabbe and Nortorp (Figure 1.2) contain scapolite. Retrograde growth of chlorite and white mica in place of biotite, alteration of hornblende along fractures and grain boundaries to chlorite and chlorite veins are all late-stage textures seen locally. Sericitization of plagioclase is ubiquitous. Moderate to strong static recrystallization textures are pervasive.

Supracrustal Gneisses

One major zone of supracrustal gneiss is found in and around the Stensjö Nature Preserve (Figure 1.2). Differential weathering emphasizes discrete 2 cm to 5 cm thick S1 layers. Leucosomes of very-coarse-grained quartz and feldspar, interlayered with aluminosilicate-bearing paleosome layers, define the dominant S1 foliation. Tight to isoclinal F3 folds asymmetrically fold the foliation (Figure

Figure 1.10. Photomicrograph of corona texture in the mafic orthogneiss. Vermicular intergrowths of clinopyroxene and quartz, hornblende, plagioclase and garnet rim orthopyroxene phenocrysts. The field of view is 13 mm across.

Figure 1.11. Photomicrograph of symplectic texture between opaque minerals, clinopyroxene, hornblende and plagioclase. Field of view is 3.3 mm across.

Figure 1.12. Garnet in a mafic orthogneiss. Note the pressure shadows on either side of the garnet. Pocket knife is 10 cm long.

First Dyke Suite (Mafic Dykes)

Mafic dykes of the first suite are polydeformed and thus the oldest undeformed dykes. These 3 cm to 1 m thick dykes intrude the orthogneiss and are parallel to sub-parallel to the S1 fabric of the gneiss package (Figures 1.3, 1.4, 1.5 & 1.15). Locally, foliations of the host orthogneiss are slightly, but distinctly, oblique to the dyke margins. Millimeter scale mafic layers comprising hornblende, biotite and garnet are interlayered with plagioclase and, less commonly, scapolite layers to define the strong compositional foliation in the

1.13). Aggregates of weakly to moderately aligned, recrystallized sillimanite needles form a moderate to strong L4 mineral lineation (Figure 1.14) that is commonly oblique to F3 fold axes. Within the Stensjö Nature Preserve, late-stage F5 folding broadly folds the L4 sillimanite mineral lineation (Table 1.1).

The mineral assemblage of the supracrustal gneiss consists of $qtz+pl+kfs+sil\pm bt\pm ms\pm hbl\pm zrn\pm ap$ (Appendix A). Biotite occurs in quartz- and feldspar-rich layers and is weakly aligned. Accessory minerals include apatite, titanite, zircon, monazite and tourmaline. Chlorite is a retrograde phase, and plagioclase has been sericitized. The mineral assemblage of the leucosomes is $pl+qtz+kfs+grt+bt\pm ms$ (Appendix A).

The supracrustal gneisses are strongly recrystallized, as indicated by dynamic and static recrystallization textures in quartz and feldspar and radial sprays of sillimanite. Locally, the supracrustal gneisses are strongly migmatized and resemble orthogneisses; however, the presence of sillimanite maintains the distinction between the supracrustal gneisses and the orthogneisses.

First Dyke Suite (Mafic Dykes)

Mafic dykes of the first suite are polydeformed and thus the oldest observed dykes. These 3 cm to 1 m thick dykes intrude the orthogneisses and are parallel to sub-parallel to the S1 fabric of the gneiss package (Figures 1.3, 1.4, 1.5 & 1.15). Locally, foliations of the host orthogneiss are slightly, but distinctly, oblique to the dyke margins. Millimeter scale mafic layers comprising hornblende, biotite and garnet are interlayered with plagioclase and, less commonly, scapolite layers to define the strong compositional foliation in the

Figure 1.14. Sillimanite lineation (L4) in the supracrustal gneiss in the Stensjö Nature Preserve. Pocket knife is 10 cm long.

Figure 1.15. Sample 2, a mafic dyke of the first dyke suite. Note the obliquity of S1 in the felsic orthogneiss (parallel to the pencil) to the dyke. N2 of the felsic orthogneiss cross-cuts the dyke and the S2 foliation.

dykes (Figure 1.5). This foliation is correlated with the parallel S2 in the gneisses. Aligned hornblende and biotite complement the compositional layering. At least one generation of leucosome (N2) occurs in the first dyke suite, generally parallel to the S2 foliation. The dykes of the first suite are commonly boudinaged, truncating the S2 foliation. The S2 foliation of the dykes is isoclinally folded (Table 1.1) with a style and orientation similar to F3 folds of N2 in the felsic orthogneiss (Figure 1.4). Folds in the first dyke suite are therefore correlated to F3 in the orthogneisses.

The mineral assemblage of the first dyke suite includes $pl+hbl\pm bt\pm cpx\pm grt\pm qtz\pm scp$ (Appendix A). Accessory minerals include zircon, apatite and opaque minerals. Biotite occurs as both a stable and a retrograde phase. Poikiloblastic garnet and hornblende occur locally; garnet includes biotite and clinopyroxene, and hornblende includes plagioclase, opaque minerals and clinopyroxene. Feldspar intergrowth textures are rare. Mineral textures indicate reactions between clinopyroxene and hornblende, and between biotite and hornblende. Chlorite and sericite are retrograde phases with chlorite replacing biotite, and sericite replacing plagioclase. Both dynamic rotational recrystallization and strong static recrystallization features occur in the first dyke suite.

Second Dyke Suite

Both felsic and mafic dykes of the second suite intrude the felsic, mafic and supracrustal gneisses and the first dyke suite. They post-date the earliest deformations, D1, D2 and D3, but predate the D4 deformation (Figure 1.3, Table

1.1). The planar fabrics in the second dyke suite vary widely in intensity and include primary and deformation-related foliations.

Mafic Dykes, Second Dyke Suite

The 15 cm to 2.5 m thick, very-fine-grained to coarse-grained, mafic dykes of the second suite contain a weak planar fabric, S4. Slight compositional variations and, to a lesser extent, aligned hornblende, biotite and elongate, anhedral garnet most commonly define S4. Aligned hornblende also defines a lineation that is correlated with L4 in the gneisses. The lack of migmatitic leucosomes and less deformed nature of these mafic dykes distinguishes them from mafic dykes of the first suite. Mafic dykes of the second suite cross-cut foliations of the migmatitic felsic, mafic and supracrustal gneisses and the first dyke suite, with discordance ranging from slightly oblique to as much as 30°. Field relationships indicate that the second mafic dykes post-date migmatization of the gneisses (Figure 1.16).

The mineral assemblage of these mafic dykes is $pl+bt+hbl\pm cpx\pm grt\pm scpt\pm qtz$ (Appendix A) with accessory opaque minerals, apatite, euhedral zircon, rutile, titanite and calcite. Two generations of biotite exist, but both are rare. Where biotite does occur, it is commonly aligned and mimics earlier foliations. Several reaction rim textures exist including ilmenite rimmed by titanite (Figure 1.17) and, more commonly, clinopyroxene rimmed by hornblende or biotite. Feldspar intergrowths occur in much of the plagioclase. Deformation textures include fractured plagioclase, plagioclase with deformed and displaced twins and kinked plagioclase.

Figure 1.16. Mafic dyke of the second suite (bottom) cross-cutting the mafic orthogneiss. Note the clear evidence that the second dyke suite post-dates the migmatization and gneiss-forming deformation in the orthogneiss. Rock hammer for scale. Photograph was taken at Gåsanabbe.

Figure 1.17. Photomicrograph of ilmenite rimmed by titanite in a mafic gneiss. Indicative of retrogression from granulite- to amphibolite-facies conditions. Field of view is 1.7 mm across.

Hornblende, garnet, clinopyroxene and scapolite have poikiloblastic textures. Hornblende has inclusions of opaque minerals, plagioclase, biotite and, less commonly, clinopyroxene. Garnets overgrow the dominant S4 foliation and include plagioclase, hornblende, opaque minerals, biotite and clinopyroxene. Clinopyroxene contains biotite, opaques, plagioclase, hornblende, garnet and rutile needles. Scapolite includes plagioclase, biotite, hornblende and titanite.

Retrograde sericitization of plagioclase commonly occurs near and along grain boundaries. Chlorite is also a retrograde phase. Recrystallization textures include rotationally recrystallized hornblende and plagioclase and, more commonly, statically recrystallized plagioclase and quartz.

Felsic Dykes, Second Dyke Suite

Felsic dykes of the second suite range from aplitic to very coarse grained, with pegmatites as the dominant variety. These dykes range from 10 cm to 2 m thick. Compositional layering of quartz and feldspar defines the main foliation, S4, of these felsic dykes. The foliation, commonly subparallel to the gneissic fabric of the host rock, cross-cuts the S1/S2 foliations of the gneiss units (Figures 1.3, 1.18 & 1.19) and S2 of the first dyke suite. The intensity of deformation varies such that some of the dykes are closed to isoclinally folded by F4 folds and others contain only weak, planar, compositional fabrics. Statically recrystallized quartz and feldspar rods and aligned biotite defined a weak to strong L4 lineation. All dykes are strongly statically recrystallized.

The mineral assemblage consists of $kfs+pl+qtz\pm grt\pm ms\pm bt\pm hbl$ (Appendix A) with accessory minerals including coarse-grained monazite, well-zoned,

Figure 1.18. Unusually high-angle contact between the mafic orthogneiss (left) and a pegmatite dyke of the second suite (right). Note the weak fabric in the dyke (S4) and the absence of migmatitic leucosomes versus the strong foliation (S1/S2) and presence of leucosomes (N2) in the gneiss. Rock hammer for scale.

Figure 1.19. Structural relationships between the felsic orthogneiss and a pegmatite dyke of the second suite. Sample 3 was extracted from the coarse-grained, dark-pink pegmatite that cross-cuts the flattened N2 leucosomes in the gray, felsic orthogneiss. This photograph shows an apophysis of the sampled dyke. Dashed lines denote margins of the pegmatite. Rock hammer (top) for scale.

ehedral zircons, rounded zircons, rutile and opaque minerals. Garnet phenocrysts reach 1 cm in diameter. Intergrowths between K-feldspar and plagioclase are pervasive. Chlorite and sericite are present as retrograde phases. Static recrystallization is pervasive.

Third Dyke Suite

The third dyke suite represents the last recognizable pulse of intrusive magmatism in the study area. These dyke cross-cut D1-D4 fabrics in all other rock types (Figure 1.3) and contain little evidence of D5 ductile deformation. Compositionally, both pegmatitic and mafic dykes are present, but the former are much more common.

Felsic Dykes, Third Dyke Suite

Pegmatitic dykes of the third suite are widespread and vary in thickness from 1 cm to 3 m. They are coarse to very coarse grained and sometimes yield macroscopic, igneous zircons (<1-5 mm). A representative mineral assemblage is kfs+pl+qtz±bt±zrn (Appendix A). These felsic dykes are commonly undeformed or brittlely tectonized and locally contain kinked biotites. They cross-cut foliations of the other units at high angles, with discordance up to 60°-70°.

Mafic Dykes, Third Dyke Suite

The mafic dykes of the third suite are very fine-grained, indurated rocks, ranging from 3 cm to 3 m wide, that cross-cut fabrics in all felsic and mafic gneiss units as well as in the second dyke suite. Their compositions comprise pl+hbl±cpx±grt±bt±ep±qtz (Appendix A) with accessory opaque minerals, titanite and apatite. Twinned plagioclase laths, a characteristic texture found in igneous

rocks, are preserved. Biotite is weakly aligned. Hornblende and garnet are locally poikiloblastic, with inclusions of plagioclase, biotite and opaque minerals. Chlorite occurs as an alteration product of biotite. Approximately 5 mm wide veins containing plagioclase, hornblende and quartz occur locally. The dykes appear unmetamorphosed in the field, but petrographic studies reveal recrystallization textures including complete static recrystallization of plagioclase and hornblende (Figure 1.20).

Figure 1.20. Photomicrograph of a statically recrystallized mafic dyke at the third dyke suite. Note the straight grain boundaries and granoblastic texture. Field of view is 3.3 mm across.

Figure 1.20. Photomicrograph of a statically recrystallized mafic dyke of the third dyke suite. Note the straight grain boundaries and equant grains. Field of view is 3.3 mm across.

Chapter 2: Mesoproterozoic tectonothermal evolution of the Ätran terrane, southwestern Sweden: New constraints from field relationships and U-Pb geochronology

INTRODUCTION

The Grenville Orogen of North America has been correlated across the present-day Atlantic Ocean with the Sveconorwegian Orogen of Scandinavia (Gower, 1990). These two orogenic belts are postulated to have formed a *ca.* 1.70 Ga contiguous southern margin of NENA (Northern Europe - North America) (Gower et al., 1990), but their relationship is complicated because formerly interposed crustal material is now missing. Ongoing studies of the Sveconorwegian Orogen that incorporate field and structural geology with reliable radiometric ages are essential to developing a better understanding of the tectonic evolution of the Baltic craton.

Orogenic events in Baltica include the *ca.* 1.6 Ga Gothian and *ca.* 1.0 Ga Sveconorwegian orogenies (Gower, 1990), and there is limited evidence for an intervening event at *ca.* 1.4 Ga "Hallandian" (Hubbard, 1975). Reworking of pre-existing crustal material during the Sveconorwegian Orogeny produced deformation fabrics that are parallel to earlier-formed fabrics. Assignment of deformation fabrics to their respective orogenic events is a challenge, but fundamental to determining the relative importance of the Gothian and Sveconorwegian orogenies in Baltica.

We have examined a small part of the Southwestern Scandinavian Domain (SSD, Gaál & Gorbatshev, 1987) in southwestern Sweden making outcrop-scale,

structural and petrographic observations and obtaining U-Pb data to help resolve discrepancies in proposed thermotectonic models. A longer-range purpose is to facilitate correlations between thermal and deformational events in southeastern Baltica and eastern Laurentia from Gothian through Sveconorwegian times.

TECTONIC FRAMEWORK OF BALTICA

The Proterozoic tectonic evolution of Baltica was dominated by westward crustal growth (present-day coordinates) away from an Archean core. The 1.95-1.75 Ga Svecofennian Orogeny created a north-south trending belt, the Svecofennian Domain (Figure 1.1) (Gaál and Gorbatshev, 1987). Subsequent eastward subduction under the Baltic craton resulted in 1.85-1.65 Ga calc-alkaline magmatism of the Transscandinavian Igneous Belt (TIB, Lindh & Gorbatshev, 1980; Larson & Berglund, 1992; Persson & Wikström, 1993) forming the western margin of Baltica. Allochthonous arcs were accreted onto this western margin (Åhäll & Gower, 1997) culminating in the 1.75-1.55 Ga collisional event (Connelly et al., 1996), termed the Gothian Orogeny.

The post-Gothian collage of deformed margin (TIB) and accreted arcs is referred to as the Southwest Scandinavian Domain (SSD) (Gaál & Gorbatshev, 1987; Connelly & Åhäll, 1996) and includes the Ätran, Klarälven and Idefjorden terranes (Åhäll & Gower, 1997) (Figure 1.1). The laterally correlated Ätran and Klarälven terranes, formerly known as the Eastern Segment, represent reworked TIB rocks outboard from which lies the allochthonous Idefjorden terrane (Figure 1.1). The Ätran and Klarälven terranes are bound on the east by the Protogine Zone and on the west by the Mylonite Zone, both representing complex ductile

shear zones. Late Gothian, syn-orogenic plutons (1.59-1.55 Ga) stitched arcs of the Idefjorden terrane and this allochthonous terrane to the Ätran terrane (Åhäll et al., 1993; Connelly & Åhäll, 1996).

Gothian orogenesis was followed by widespread inter-orogenic magmatism, sedimentation and rift-related tectonism from *ca.* 1.5 Ga to *ca.* 1.2 Ga (Gorbatshev et al., 1987; Gower et al., 1990; Åhäll & Gower, 1997; Åhäll & Connelly, in press). The episode of inter-orogenic magmatism at *ca.* 1.4 Ga resulted in charnockite bodies and abundant felsic and mafic dykes and may be related to the so-called "Hallandian Orogeny" (Hubbard, 1975). "Hallandian-aged" deformation has been suggested by Hubbard (1976) and Talbot & Heeroma (1989), although, thus far, U-Pb ages from zircons and titanites (Lundqvist et al., 1992; Connelly et al., 1996; Söderlund, 1996) support only a thermal event at this time. Talbot & Heeroma (1989) speculate that deformation near Varberg (Figure 1.2, inset) corresponds to the "Hallandian Orogeny," but deformation associated with this proposed event is not yet understood nor agreed upon.

The SSD was reworked and telescoped during the *ca.* 1.2-0.9 Ga Sveconorwegian Orogeny (Gower, 1990; Hoffman, 1992), the last major event recorded in the SSD. Relatively minor amounts of juvenile crustal material were also added during the Sveconorwegian Orogeny. Early Sveconorwegian contractional deformation was followed by extensional collapse and exhumation of mid-crustal rocks along pre-existing terrane boundaries (Johansson et al., 1991; Connelly et al., 1996; Åhäll & Gower, 1997). Sveconorwegian deformation and metamorphic overprinting were so substantial that some researchers have referred

to the SSD as the Sveconorwegian Province (Gower, 1985; Berthelsen, 1980). We refer to this area as the SSD in recognition of its polydeformed nature.

Parallel to sub-parallel fabrics in the SSD resulting from the Gothian and Sveconorwegian orogenies are nearly indistinguishable without careful examination. Despite this complication, differentiation of Gothian and Sveconorwegian fabrics has been accomplished in some parts of the SSD using cross-cutting relationships between different generations of intrusive rocks (Samuelsson & Åhäll, 1985; Larson et al., 1986; Åhäll et al., 1990; Connelly et al., 1996). Disputes still exist, however, regarding the timing of the migmatization and regional gneiss-formation in the SSD (Åhäll, 1996; Connelly & Åhäll, 1996; Connelly et al., 1996; Johansson et al., 1996; Åhäll et al., 1997b; Möller & Söderlund, 1997). Ages obtained using U-Pb (Söderlund, 1996; Söderlund et al., 1996; Wang et al., 1997), Sm-Nd (Johansson et al., 1991; Johansson & Kullerud, 1993; Wang et al., 1996) and Ar-Ar (Page et al., 1996; Wang et al., 1996, 1997) geochronology, have been interpreted to date a Sveconorwegian gneiss-forming event. In contrast, detailed field mapping and U-Pb geochronology by Connelly & Åhäll (1996), Connelly et al. (1996), Larson (1996) and this study indicate that migmatization and associated deformation occurred primarily during the Gothian Orogeny.

The Ätran Terrane

The Ätran terrane (Figure 1.1) has been mapped at 1:200,000 scale by the Swedish Geological Survey. This terrane comprises mostly 1.70-1.66 Ga, amphibolite- to granulite-facies, felsic and mafic, polydeformed orthogneisses

that are polydeformed equivalents of the TIB rocks (Lindh & Gorbatschev, 1980; Larson et al., 1990; Wahlgren et al., 1994; Connelly et al., 1996; Söderlund et al., 1996). These veined and migmatized orthogneisses have varied compositions including tonalites, granodiorites, quartz-monzonites and granites (Connelly et al., 1996).

Abundant amphibolite- to granulite-facies mafic, granitic and pegmatitic dykes cross-cut the Ätran terrane orthogneisses. Among these, amphibolite-facies dykes yield a wide range of ages, from 1.61 Ga to 1.22 Ga (Berglund & Connelly, 1994; Connelly et al., 1996). A number of structural and geochronologic studies in the Ätran terrane (Welin, 1994; Andersson, 1996; Connelly et al., 1996; Lindh, 1996; Page et al., 1996; Söderlund, 1996; Wang et al., 1996, 1997) have attempted to partition structural and metamorphic elements between the Gothian and Sveconorwegian orogenies. 1612 ± 8 Ma aplitic dykes (Connelly et al., 1996) that cross-cut orthogneisses in the northern Ätran terrane provide the earliest constraint on the timing of Gothian deformation and migmatization in this terrane. Despite the different schools of thought regarding the timing of the major gneiss-forming deformation, it is widely accepted that granulite-facies conditions were locally attained in the Ätran terrane during the Sveconorwegian Orogeny (Johansson et al., 1991; Johansson & Kullerud, 1993; Wang et al., 1997).

The Mylonite Zone

The west-dipping Mylonite Zone (MZ) is a high-grade shear zone that forms the boundary between the upper-amphibolite- to granulite-facies rocks of the Ätran terrane and amphibolite-facies rocks of the Idefjorden terrane (Figure

1.1). Because of the close proximity of this zone to the present study area, it may be locally important. Different studies have suggested a variety of scenarios for the structural history of the kinematically complex MZ (Talbot & Heeroma, 1989; Park et al., 1991; Berglund, 1997). The MZ may be a more ancient zone of weakness, perhaps a Gothian suture between the Ätran and Klarälven terranes and the Idefjorden terrane (Berthelsen, 1980; Gorbatshev, 1980; Park et al., 1991; Åhäll, 1995; Page et al. 1996), or a *ca.* 1.4 Ga “Hallandian” shear zone, as proposed by Talbot & Heeroma (1989).

The break in metamorphic grade across the MZ implies that extension along the zone played a fundamental role in the Sveconorwegian uplift history of the Ätran terrane (Johansson et al., 1991). These authors and Connelly et al. (1996) suggested that the rocks west of the MZ were thrust over the Ätran terrane during the Sveconorwegian Orogeny. Isostatic uplift (Talbot & Heeroma, 1989) and/or gravitational collapse and thermal relaxation of overthickened crust (Larson et al., 1990; Park et al., 1991; Berglund & Connelly, 1994) may explain late Sveconorwegian extension along the MZ.

GEOLOGY OF THE FALKENBERG-HALMSTAD REGION

This study focuses on the coastal region of the Ätran terrane between Falkenberg and Halmstad (Figure 1.2) that comprises amphibolite- and granulite-facies rocks, first identified by Quensel (1951). A number of structural and geochronologic studies (Welin, 1994; Åhäll, 1996; Andersson, 1996; Lindh, 1996; Page et al., 1996; Söderlund, 1996; Wang et al., 1996, 1997) have

attempted to divide structural and metamorphic elements between the Gothian and Sveconorwegian orogenies.

LITHOLOGIES

The study area comprises four major rock units (Table 1.1). Dominant interlayered felsic, intermediate and mafic orthogneisses are the oldest. Two generations of leucosomes, N1 and N2, define the gneissic layering in the orthogneisses (Figures 1.3 & 1.4). A third, coarser-grained, less deformed migmatitic leucosome (N3) is locally present in the felsic orthogneiss (Figure 1.5). N1 and N2 migmatization was accompanied by deformation that transposed primary igneous features. Approximately 3 km² of felsic orthogneiss near Skipås (Figure 1.2) escaped migmatization and much of the gneiss-forming deformation, resulting in a more massive, granitic appearance. These rocks are referred to as the Skipås granite.

At least three younger generations of dykes intrude the orthogneisses (Figure 1.3). Dykes of the *first dyke suite* are polydeformed mafic dykes that are parallel to sub-parallel to the earliest fabric (Figures 1.4, 1.5 & 1.15). Coarse-grained leucocratic material that occurs in the first dyke suite is correlated with the N2 phase of the host orthogneiss.

Felsic (chiefly pegmatitic) and mafic dykes of the *second dyke suite* intruded the orthogneisses and cross-cut earlier structural fabrics (Figures 1.3, 1.16, 1.18, 1.19). D4 deformational fabrics dominate in the second dyke suite and vary in intensity.

The *third dyke suite* comprises pegmatitic and mafic dykes and represents the last pulse of magmatism. These dykes intrude all other rock types, cross-cut D1-D4 deformation fabrics and some contain little evidence of D5 deformation (Figure 1.3).

STRUCTURE

Five major phases of ductile deformation (D1-D5) are identified in the study area (Table 1.1). The earliest, D1, affected the orthogneisses and resulted in the first foliation, S1. S1 in the felsic orthogneiss is defined by compositional layers of leucocratic quartzo-feldspathic layers (N1), melanocratic hornblende- and biotite-rich layers and gray, paleosome layers (Figures 1.3 & 1.4). Aligned minerals locally define S1 in the mafic orthogneiss. S1 is cross-cut by N2 and all three dyke suites (Figures 1.15, 1.16, 1.18 & 1.19).

The second phase of deformation, D2, enhanced the foliation in the orthogneisses and flattened N2 creating a composite S1/S2 foliation (Figure 1.4; Table 1.1). D2 also produced an S2 compositional layering in the first dyke suite, defined by hornblende-biotite-garnet layers and plagioclase-rich leucocratic layers (N2) (Figure 1.5). Aligned hornblende and biotite compliment the S2 compositional layering. In addition to producing a foliation, late-stage D2 deformation resulted in boudinage of the first dyke suite with N2 leucosomes of the felsic orthogneiss filling the interboudin spaces. Thus, both N2 leucosomes formed and were flattened during D2. The second and third dyke suites cross-cut S2.

Closed to isoclinal folds (F3) of both S1/S2 of the gneisses and S2 of the first dyke suite characterize the third phase of deformation, D3 (Figures 1.4 & 1.13; Table 1.1). Realigned quartz and feldspar augen locally define a weak F3 axial planar foliation (S3). The slight discordance of S3 with earlier foliations makes it difficult to differentiate between S1/S2 and S3 in the field in the absence of F3 folds. Thus, on the limbs of F3 folds, D3 resulted in a composite S1/S2/S3 foliation. The second and third dyke suites are not observed to cross-cut D3 structures.

The fourth phase of deformation, D4, affected the gneisses and the first and second dyke suites and produced structures that are parallel to subparallel to those of D1-D3. D4 structures include an S4 foliation that is axial planar to F4 open to isoclinal folds, and a regional L4 lineation, as noted by Åhäll (1996) (Table 1.1). F4 folds refold F3 folds. S4, most easily seen in the second dyke suite, is commonly defined by compositional layers and locally defined by mineral alignment. S4 is typically subparallel to but unequivocally cross-cutting the composite foliation of the host gneiss (Figures 1.16 & 1.18). L4, typically south to southeast plunging, is most commonly a mineral elongation or alignment. Felsic, pegmatitic dykes of the second suite and felsic and intermediate gneisses display a strong to weak L4. The third dyke suite cross-cuts D4 structures.

The last phase of deformation, D5, affected the gneisses, the first and second dyke suites and some dykes of the third suite (Table 1.1). D5-related shear zones locally cross-cut the gneisses and the second dyke suite. D5 reoriented D1-D4 fabrics by broad, open F5 folds with north trending fold axes. D5 structures are not ubiquitous in the dykes of the third suite, however some are

folded (F5). Later, brittle deformation affected some dykes of the third suite, but many of these dykes are undeformed.

METAMORPHISM

Little can be determined about the nature of pre-Sveconorwegian metamorphism because mineral assemblages and recrystallization textures in rocks throughout southwestern Sweden formed during the Sveconorwegian Orogeny (Johansson et al., 1991; Johansson & Kullerød, 1993; Wang et al., 1997). Field relationships between N1 and N2 leucosomes and the cross-cutting dykes of the second dyke suite, and geochronologic evidence discussed below, however, support Gothian-aged migmatization, indicating that temperatures were high enough to induce partial melting at that time. The association of N1 and N2 with the D1 and D2 deformation phases, respectively, suggest that Gothian migmatization was attendant with D1 and D2 deformations.

F3 fold style weakly constrains the metamorphic conditions during D3. Both mafic dykes of the first suite and N2 in the felsic orthogneiss form passive F3 folds, indicating similar rheological behavior. Such similar rheological properties in rocks with such varied compositions suggests that D3 deformation occurred at high temperatures.

Maximum Sveconorwegian-aged P-T conditions estimated by Johansson et al. (1991) for the southernmost part of the present study area are 10.5 kbar and 705°C. Isotopic studies by Johansson et al. (1991), Page et al. (1996), Söderlund (1996) and Wang et al. (1997) in this area provide a wide range of ages from *ca.* 1.0 Ga to *ca.* 0.9 Ga. We have been able to substantiate reported granulite-facies

assemblages in the area (Söderlund, 1993, 1996; Johansson et al., 1996) in only one locality; otherwise the assemblages are amphibolite- to upper-amphibolite-facies.

In the one exceptional occurrence, 3 cm orthopyroxene porphyroblasts with corona textures suggest granulite-facies conditions with retrogression to amphibolite- or upper-amphibolite-facies. The 1 cm coronas include, from core outward, vermicular intergrowths of clinopyroxene and quartz, rimmed by hornblende, quartz, garnet and plagioclase (Figure 1.10). Opaque minerals locally display a symplectic texture comprising clinopyroxene, hornblende and plagioclase (Figure 1.11). Possible reactions that would produce these disequilibrium textures include $pl+opx \rightarrow grt+qtz$ or $pl+hbl \rightarrow grt+qtz+H_2O$.

Other mineral textures in mafic rocks suggest retrograde reactions such as 1) $hbl+qtz \rightarrow bt+pl$, 2) $grt+qtz \rightarrow pl+H_2O$ and Ca-rich fluid and 3) $cpx+Ca\text{-rich } pl+H_2O \rightarrow hbl+Na\text{-rich } pl$. Ilmenite rimmed by titanite indicates a local breakdown reaction of ilmenite to titanite (Figure 1.17). Ilmenite is common in granulite-facies orthogneisses (Deer et al., 1992), thus its breakdown is consistent with granulite-facies conditions and subsequent retrogression.

Recrystallization textures indicate minimum peak metamorphic conditions. Dynamic recrystallization textures seen in many felsic rocks include migrationally recrystallized quartz, minor amounts of migrationally recrystallized feldspar, and rotationally recrystallized quartz and feldspar. Such textures are common to upper-amphibolite- to granulite-facies rocks. Pervasive static recrystallization of quartz and feldspars (Figures 1.7 & 1.20) implies that metamorphism continued after Sveconorwegian deformation ceased.

GEOCHRONOLOGY

Having established the relative timing of events using field relationships, U-Pb geochronology was employed to gain a better understanding of the tectonothermal development of the region. Geochronology samples were selected to determine and/or constrain ages of magmatism, migmatization and metamorphism. Specific objectives were: 1) determine the crystallization age of the protolith of the felsic gneiss unit, 2) determine the age of metamorphism of the mafic gneisses, 3) constrain the timing of emplacement and metamorphism of the first dyke suite, 4) verify the *ca.* 1.4 Ga crystallization age of the second dyke suite as previously determined by Söderlund (1996), 5) resolve the timing of the regional gneiss-forming event, 6) constrain the timing of Sveconorwegian deformation as related to the crystallization of an undeformed dyke from the third dyke suite and 7) estimate the rate of late- to post-Sveconorwegian cooling. Appendix B outlines U-Pb analytical procedures; sample locations follow the sample numbers below and are given using coordinates of the Swedish National Grid.

Analytical Results

Paleosome, Sample 1 (629740/130691)

Sample 1, a gray, homogeneous layer in the felsic gneiss, representing its paleosome, was collected from an abandoned coastal quarry near Särö (Figure 1.2). Abundant leucosomes and veins were carefully avoided during sampling. Zircon morphologies range from euhedral, prismatic and elongate grains to anhedral ellipses and spheres. Cores, apparent using petrographic and

cathodoluminescence (CL: Appendix C) microscopy, are common in the euhedral grains, and care was taken to avoid grains containing them. Titanite occurs as light orange to medium brown fragments.

U-Pb isotopic data (Table 2.2) from five clear, colorless fractions (Z1, Z3, Z4, Z5, Z6) of euhedral igneous zircons (Figure 2.21, CL inset), 2 μg (single grain) to 40 μg , define a discordia line with an upper intercept (U.i.) of 1659 ± 5 Ma and a lower intercept (L.i.) of $872 + 71 / - 66$ Ma (probability of fit 12%; Figure 2.21). In spite of the statistically acceptable regression of this line, data from zircon fractions Z5 and Z6 plot concordantly at 1664 ± 4 Ma, a value located within the estimated error for the U.i. Therefore, 1664 ± 7 Ma is preferred and is interpreted to represent the crystallization age of the igneous protolith.

Two titanite fractions yield a concordant age of 932 ± 7 Ma (Figure 2.21, inset) that reflects local metamorphism. Estimated closure temperatures for the U-Pb system in titanite range widely from 450°C to $>700^\circ\text{C}$ (Mattinson, 1978; Gascoyne, 1986; Tucker et al., 1987; Heaman & Parrish, 1991; Mezger et al., 1991; Mezger et al., 1993; Scott & St-Onge, 1995; Zhang & Schärer, 1996). Concordant data from the two titanite fractions agree within error with the L.i. for the zircon regression at 932 ± 7 Ma, interpreted as the age of metamorphism that resulted in Pb loss in zircon.

Data from zircon fractions Z2 and Z7 (Figure 2.21) plot above the discordia line. These fractions possibly experienced multi-stage Pb loss and/or overgrowth during one or more metamorphic events preceding *ca.* 932 Ma.

Table 2.2. U-Pb isotopic data.

Codes in fraction numbers are: M, monazite; R, rutile; T, titanite; Z, zircon.

Abbreviations are: abr, abraded; bm, brown; clr, clear; dk, dark; el, elongate; eq, equant; euh, euhedral; frac, fractures; frag, fragments; incl, inclusions; ir, irregular; lt, light; lg, large; med, medium; need, needles; pk, pink; prsm, prism; rnd, round; sm, small; v, very; yw, yellow.

* Ratios corrected for fractionation, 2-3 pg laboratory Pb blank, initial common Pb calculated using Pb isotopic compositions of Stacey and Kramers (1975) and 1 pg U laboratory blank. Two-sigma uncertainties on isotopic ratios, calculated with a modified unpublished error propagation program written by L. Heaman, are reported after the ratios and refer to the final digits.

Figure 2.21. Concordia diagram for sample 1, zircon (Z) and titanite (T; inset). Below the sample label is a CL image of an igneous zircon from sample 1 showing euhedral growth zoning. See text for discussion.

Mafic Dyke, First Dyke Suite, Sample 2 (629748, 130693)

As mentioned, mafic dykes of the first suite are more intensely deformed than the younger dykes, and their trends are essentially parallel to the regional gneissic foliation. Sample 2, collected near sample 1 (Figure 1.2), is from a black, strongly foliated (S2) amphibolite dyke (Figure 1.15) with minor partially retrogressed clinopyroxene. It is boudinaged and is traceable for approximately 15 meters. Intense recrystallization obscures the discordance between the dyke trend and the local foliation of the felsic gneiss. A coarse-grained N2 leucosome cross-cuts S2 of the sampled dyke.

Analyzed zircon fractions comprised small (50 μm), clear, colorless, rounded and spherical to elliptical grains (Table 2.2). These are metamorphic morphologies, an interpretation reinforced by the CL-imaged irregular zoning patterns (Figure 2.22, inset). A regression through data from four of the five fractions yields an U.i. of 1654 ± 9 Ma (probability of fit 10%; Figure 2.22), interpreted as a metamorphic age. The L.i., 941 ± 30 Ma, is interpreted as a product of Sveconorwegian Pb loss. Excluded from the regression is the datum for fraction Z5, that lies below the discordia line and is interpreted to indicate an inherited component.

Pegmatite Dyke, Second Dyke Suite, Sample 3 (629729/130691)

Sample 3 is a coarse-grained and strongly lineated (L4) pegmatite collected from an approximately 30 m³ outcrop near the sample 1 and 2 localities (Figure 1.2). The pegmatite cross-cuts the fabric (S1/S2) of the host felsic gneiss

Figure 2.22. Concordia diagram for sample 2, zircon (Z). Inset is a CL image of a metamorphic zircon from sample 2. See text for discussion.

(Figure 1.19), and was collected to determine the igneous crystallization age of the pegmatite and to constrain the crystallization age of N2 and the timing of D2 and D4.

Sample 3 yielded mineral separates of zircon, monazite and rutile. Zircon morphologies include large euhedral to rounded prisms, elongate crystals and crystal fragments. The sample yielded two morphologies of monazite: large, light yellow, anhedral, fragile crystals with distinct cleavage planes and large, light to dark yellow, anhedral, blocky, robust grains lacking cleavage planes. Medium to large (75-100 μm), clear, gold to orange, euhedral and multi-faceted rutile grains were rare.

CL images indicate primary growth zoning in large, clear, colorless, euhedral, prismatic grains and fragments of analyzed zircon (Table 2.2). Regression through data from four fractions yields $1426 \pm 9/-4$ Ma (U.i.) and $517 \pm 307/-227$ Ma (L.i.) (probability of fit 26%; Figure 2.23). The U.i. is interpreted to represent the igneous crystallization age of the pegmatite. In the context of the known geologic history of the region, the L.i. is possibly a consequence of progressive and/or multi-stage Pb loss.

Copeland et al. (1988), Parrish (1990) and Mezger et al. (1991) maintain that monazite forms during moderately high-grade metamorphism ($T = 640^\circ\text{--}750^\circ\text{C}$), and that monazite U-Pb ages refer to cooling through amphibolite facies (Copeland et al., 1988). Data from five monazite fractions produce a mixing line between 1410 ± 9 Ma (U.i.) and 948 ± 4 Ma (L.i.) (probability of fit 60%; Figure 2.23, inset). Fractions M3-M6 are single-grain analyses that indicate two separate events. The first, dated by the fragile crystal morphology at 1410 ± 9 Ma, most

Figure 2.23. Concordia diagram for sample 3, zircon (Z), monazite (M; inset) and rutile (R; inset). See text for discussion.

likely represents the age of monazite crystallization during the initial cooling of the pegmatite. The second event was dated by three fractions (M4-M6) of robust, blocky crystals that provide a Sveconorwegian metamorphic age of 948 ± 4 Ma. Fraction M2 consisted of three grains that most likely comprised both monazite generations as its datum plots in an intermediate position on the discordia line.

The U-Pb system in rutile is easily reset and is expected to reflect either late hydrothermal activity (Machado et al., 1989) or cooling below the closure temperature that has been calculated by Mezger et al. (1989) to range from 380°C to 420°C , depending on grain radius. Two rutile fractions yield a late- to post-Sveconorwegian cooling age of 878 ± 10 Ma (Figure 2.23, inset).

Pegmatite Dyke, Second Dyke Suite, Sample 4 (630075, 130495)

Sample 4, a pegmatitic, quartzo-feldspathic dyke of the second suite was collected from the Stensjö Nature Preserve (Figure 1.2, Figure 2A in Åhäll, 1996, p. 191). The pegmatite cross-cuts S1/S2 of the host felsic gneiss and has a weak compositional foliation (S4). Determination of a crystallization age constrains the timing of D1 and D2 deformations affecting the host gneiss and the timing of S4 formation in the dyke.

Zircon morphologies include large, rounded, clear, colorless, equant grains that are commonly cracked. Data from U-Pb analyses of three zircon fractions yield a discordia line with an U.i. of $1399 \pm 7/-6$ Ma and a L.i. of $988 \pm 33/-32$ Ma (probability of fit 12%; Figure 2.24). The U.i. age is interpreted to refer to crystallization of the dyke.

Figure 2.24. Concordia diagram for sample 4, zircon (Z). See text for discussion.

Mafic Gneiss, Sample 5 (630157, 130450)

Mafic orthogneiss sampled at Gåsanabbe, immediately outside the Stensjö Nature Preserve (Figure 1.2), is a fine-grained, black, hornblende-clinopyroxene-garnet-biotite-scapolite amphibolite with compositional layers defining S1/S2. Effort was made to avoid leucosomes during sample collection.

Four zircon fractions, each with 30 to 100 very-small to small, clear, colorless, rounded, equant, anhedral grains (Table 2.2), define a discordia line from $1438 \pm 12/-8$ Ma (U.i.) to 855 ± 100 Ma (L.i.) (probability of fit 22%; Figure 2.25). Sector zoning detected by CL microscopy, supports a metamorphic origin for these zircons. The U.i. is interpreted to represent the age of new zircon growth during metamorphism. The discordance (maximum 18%) of zircon fractions Z1, Z2, Z4 and Z5 indicates Pb loss. The L.i. potentially reflects a Sveconorwegian age, but may also represent multi-stage Pb loss during the Sveconorwegian Orogeny and again more recently.

Two fractions of very-large ($>100 \mu\text{m}$), clear, dark brown to light yellow, anhedral, rounded and fragmented titanite yield a concordant age of 935 ± 5 Ma (Figure 2.25, inset), constraining more tightly the age of Sveconorwegian metamorphism.

Pegmatite Dyke, Third Dyke Suite, Sample 6 (630080, 130509)

Sample 6, collected in the Stensjö Nature Preserve (Figure 1.2), belongs to the third dyke suite. It escaped ductile deformation, but it is brittlely tectonized, with kinked biotites. Very large (1-5 mm), inclusion-rich, euhedral zircons

Figure 2.25. Concordia diagram for sample 5, zircon (Z) and titanite (T; inset). See text for discussion.

(Figure 2.26, inset) from this quartzo-feldspathic pegmatite were extracted from the outcrop by hand. The dyke is traceable for approximately 10 meters, and it clearly cross-cuts S4 in a mafic dyke of the second suite.

One large (4 mm), colorless to light-pink zircon was crushed, and three fragments were analyzed. Data from concordant fraction Z3 provides an igneous crystallization age of $946 \pm 6/-4$ Ma (Figure 2.26). A reference line from 946 Ma to 0 Ma plots through the data.

Skipås Granite, Sample 7 (629975, 130600)

Sample 7 (Figure 1.2) is a coarse-grained quartzo-feldspathic rock lacking migmatitic fabrics and exhibiting only a strong linear fabric (L4) defined by quartz rods and elongate feldspars. Because the relationship between the Skipås granite and the more deformed felsic orthogneisses is not observed in the field, its crystallization age relative to that of the host gneisses is problematical. Zircons with a wide range of morphologies were extracted, including small to large, clear to inclusion-rich and/or highly fractured, colorless to light yellow, anhedral to euhedral, equant to elongate grains. Some crystals contain obvious cores. Four zircon fractions comprising small to medium, colorless, subhedral to euhedral grains with few inclusions were analyzed. The data points do not produce a well-defined discordia line (Figure 2.27), the $^{207}\text{Pb}/^{206}\text{Pb}$ ages for the four fractions ranging from 1582 Ma to 1656 Ma.

Figure 2.26. Concordia diagram for sample 6, zircon (Z). The inset shows grains similar to the analysed grain. The wire at the right is ~1 cm in length. See text for discussion.

Figure 2.27. Concordia diagram for sample 7, zircon (Z). See text for discussion.

DISCUSSION

Timing of Orthogneiss Protolith Magmatism

The granitoid orthogneisses of the Ätran terrane have been interpreted to represent a polydeformed westward extension of TIB granitoid rocks (Figure 1.1) (Lindh & Gorbatshev, 1980; Larson et al., 1990; Wahlgren et al., 1994; Connelly et al., 1996). The 1664 ± 7 Ma igneous crystallization age for the protolith to the felsic gneisses (Table 1.1) coincides with protolith ages in other parts of the Ätran terrane and extends the recognized limit of TIB-aged protoliths westward. Despite the complexities in dating the Skipås granite, it is also interpreted as a product of this pre-Gothian magmatism that remained unaffected by Gothian deformation.

Gothian Metamorphism and Deformation

Slight obliquity between the first dyke suite and S1 of the orthogneisses (Figure 1.15) suggests that D1 and the first event of migmatization preceded emplacement of the first dyke suite. According to zircon data, the first dyke suite was metamorphosed at 1654 ± 9 Ma and was emplaced between 1664 ± 7 Ma and 1654 ± 9 Ma (Table 1.1), at an age indistinguishable from the age of the orthogneiss protolith and formation of S1 and N1. D1 and its associated migmatization must therefore be assigned to the Gothian Orogeny.

N2 formed during post-D1 metamorphism and cross-cuts N1 and S1. This metamorphism is assumed to correspond to metamorphic zircon growth in the first dyke suite (sample 2). Thus, N2 is interpreted to have formed

contemporaneously with the zircon at 1654 ± 9 Ma (Table 1.1). Field relationships between N2 and the first dyke suite indicate that N2 formed during D2; thus D2 occurred at 1654 ± 9 Ma, during the Gothian Orogeny.

Determination of Gothian P-T conditions is precluded by high-grade post-Gothian recrystallization. Gothian-aged migmatization in mafic rocks suggest that metamorphic conditions during D1 and D2 were at least at upper-amphibolite-facies given that the temperatures required to induce partial melting in mafic rocks is greater than 650°C (Clemens & Vielzeuf, 1987; Sawyer, 1991; Peacock et al., 1994).

Timing of Inter-orogenic Magmatism and Metamorphism

New data indicate a thermal event in southwestern Sweden between $1438 \pm 12/-8$ Ma and $1399 \pm 7/-6$ Ma. It coincides with the suggested "Hallandian Orogeny" (Hubbard, 1975); whether there was associated deformation remains unknown.

Igneous crystallization ages $1426 \pm 9/-4$ Ma and $1399 \pm 7/-6$ Ma from pegmatite samples 3 and 4 represent the local maximum and minimum ages for the magmatic component of the thermal event (Table 1.1). Large charnockites to the north yield ages of *ca.* 1.4 Ga (Åhäll et al., 1992; Åhäll et al., 1997a), indicating that magmatism was regional. Neither the charnockites nor the *ca.* 1.4 Ga dykes in the Falkenberg-Halmstad area were subsequently migmatized (Åhäll, 1996), although the dykes themselves may be products of migmatization. If so, this could account for local occurrences of N3 leucosomes (Figure 1.5).

We now have definite evidence that metamorphic recrystallization was coeval with the inter-orogenic magmatism, supported by evidence for new zircon growth in the mafic gneiss (sample 5) at $1438 \pm 12/-8$ Ma, during amphibolite- to upper-amphibolite-facies metamorphism.

An interesting observation is that the sampled mafic gneiss yields a younger metamorphic age ($1438 \pm 12/-8$ Ma) than the mafic dyke of the first suite (1654 ± 9 Ma), given that both must have been present at *ca.* 1.65 Ga. This difference in timing of zircon growth may be linked to the breakdown of orthopyroxene that may have been controlled by 1) compositional differences between the two rocks, 2) different points in P-T space, and/or 3) differences in the activity of H_2O .

Timing of D3

As discussed above, F3 folds are refolded by F4 folds. This constrains the timing of D3 to between 1654 ± 9 Ma, the age of D2, and $1426 \pm 9/-4$ Ma, the maximum age for D4 (discussed below) (Table 1.1). Thus, D3 most likely occurred during the Gothian Orogeny.

Timing of Sveconorwegian Effects

D4 must have occurred between the crystallization age of pegmatite sample 3 (*ca.* 1.4 Ga) and the crystallization age of the post-D5, undeformed pegmatite sample 6 (*ca.* 0.94 Ga) (Table 1.1). Deformation associated with the *ca.* 1.4 Ga “Hallandian” thermal event can not be ruled out. Poorly known timing of deformation of the second dyke suite must be post-Gothian. We interpret the

timing of D4 to be Sveconorwegian, the only locally and regionally known, post-1426 Ma event.

Earlier isotope studies of the Sveconorwegian Orogeny in southwestern Sweden (Johansson et al., 1991; Johansson & Johansson, 1993; Cornell et al., 1996; Page et al., 1996; Söderlund, 1996; Wang et al., 1997) have pointed to a 990 to 900 Ma age for Sveconorwegian upper-amphibolite- to granulite-facies metamorphism, consistent with metamorphism in the Falkenberg-Halmstad area between $988 \pm 33/-32$ Ma (Pb loss from pegmatite sample 3 zircons) and 932 ± 7 Ma (recrystallization of titanite in sample 1). Three other Sveconorwegian metamorphic ages from the study fall between within this range. In spite of well-documented granulite-facies conditions, Sveconorwegian metamorphism did not cause partial melting, probably due to earlier dehydration during the Gothian Orogeny. Pervasive static recrystallization textures, also noted by Johansson et al. (1996) elsewhere in the Ätran terrane, developed during the Sveconorwegian orogeny (Figures 1.7 & 1.20).

Closure temperatures for retention of Pb in monazite, titanite and rutile bear upon the history of cooling at the end of the Sveconorwegian Orogeny. These are estimated to be 720°C for monazite (Copeland et al., 1988; Parrish, 1990; Mezger et al., 1991), 550°-650°C for titanite (Gascoyne, 1986; Tucker et al., 1987; Heaman & Parrish, 1991; Mezger et al., 1991; Mezger et al., 1993) and 380°-420°C for rutile (Mezger et al., 1989), leading to calculated cooling rates of 4.5-11°C/million years between 948 Ma and 932 Ma, and 2.5-5°C/million years between 932 Ma and 878 Ma, depending upon choice of closure temperatures. As shown by Mezger et al. (1991) for the Adirondacks, such slow cooling rates

indicate slow (passive?) exhumation of the Ätran terrane, possibly driven by erosion and collapse of the Sveconorwegian Orogen. In other parts of the world, such as Taiwan and the Himalayas, rapid cooling rates of 70°-460°C/million years are attributed to large-scale, active extensional and contractional tectonic processes (Liu, 1982; Foster et al., 1994; Adriessen & Zeck, 1996; Chen et al., 1996).

SUMMARY

Field relationships and U-Pb ages constrain the timing of Mesoproterozoic magmatism, metamorphism and deformation in southwestern Sweden between Falkenberg and Halmstad. The 1664 ± 7 Ma felsic gneiss protolith age (sample 1) extends the known area for coeval magmatism in the TIB and the Ätran terrane farther west than previously recognized. This age and the metamorphic age of the mafic dyke (sample 2) constrain the emplacement age of the first dyke suite and the timing of the first migmatization (N1) and D1 deformation to between 1664 ± 7 Ma and 1654 ± 9 Ma, during the Gothian Orogeny. Metamorphism, migmatization (N2) and D2 deformation of the orthogneisses and the first dyke suite occurred at 1654 ± 9 Ma. D3 is constrained to between 1654 ± 9 Ma and $1426 \pm 9/-4$ Ma, suggesting that D1-D3 were all a result of the Gothian Orogeny.

U-Pb zircon crystallization ages for the sample 3 ($1426 \pm 9/-4$ Ma) and sample 4 ($1399 \pm 7/-6$ Ma) pegmatites, combined with previous data for the 1409 ± 20 Ma Glassvik pegmatite by Söderlund (1996), indicate that local magmatism occurred at *ca.* 1.4 Ga. More importantly, the $1438 \pm 12/-8$ Ma metamorphic zircon age obtained for the Gothian-derived mafic gneiss is the first

evidence reported for metamorphism at this time in southwestern Sweden. Both magmatism and metamorphism between $1438 \pm 12/-8$ Ma and $1399 \pm 7/-6$ Ma indicate high heat flow and thus represent a regional thermal event. This thermal event supports previous suggestions of a high-temperature "Hallandian" metamorphic event. Deformation associated with this thermal event has not been demonstrated.

The crystallization age of the undeformed pegmatite constrains the end of D4 deformation locally to between $1426 \pm 9/-4$ Ma and $946 \pm 6/-4$ Ma, but a Sveconorwegian age is favored. As determined by field relationships and geochronology, the main gneiss-forming event in the study area occurred during the Gothian Orogeny. In comparison, local Sveconorwegian deformation effects are subordinate.

Static recrystallization textures indicate that metamorphism persisted after deformation ceased. Metamorphic monazite (948 ± 4 Ma), titanite (932 ± 7 Ma and 935 ± 5 Ma) and rutile (878 ± 10 Ma) also indicate that temperatures in the study area remained high until at least 878 ± 10 Ma. The progressive younging of these mineral ages combined with their closure temperatures reflect slow cooling rates during isostatic unroofing of the Sveconorwegian Orogen.

Appendix B: U-Pb Techniques

Seven approximately 10 kg samples for geochronology were crushed, and standard mineral separation techniques were employed at the University of Texas at Austin to obtain mineral separates of zircon, titanite, monazite and rutile.

U-Pb analyses were performed at the University of Texas at Austin. Separated mineral fractions were carefully picked and selected based on optical properties using binocular and petrographic microscopes and morphological distinctions upon the basis of cathodoluminescence (CL) microscopy (Appendix C). Grains with inclusions and fractures, identified optically, were eliminated. Masses of analyzed fractions ranged from 2 μg to 181 μg .

All fractions were air-abraded using the technique of Krogh (1982), then re-examined and cleaned with distilled 4N nitric acid, quartz-distilled water and distilled acetone. Grains were weighed into Teflon® dissolution bombs with a mixed $^{205}\text{Pb}/^{235}\text{U}$ isotopic tracer and dissolved with HF and HNO_3 acids. For zircon analysis, U and Pb chemical separation was accomplished using minicolumns (100 μl resin volume) following the procedure of Krogh (1973). Pb blanks were 1-2 picograms. For titanite analysis, HBr chemistry was employed using 120 μl columns with a procedural blank of 2-3 picograms. U and Pb were loaded together onto outgassed, zone-refined rhenium filaments using silica gel and phosphoric acid.

Isotopic analyses were performed on a Finnigan MAT 261 thermal ionization mass spectrometer in static and/or peak jumping mode depending on

sample size and Pb concentrations. In the peak jumping mode, ^{204}Pb was measured in the axial secondary electron multiplier (SEM)/ion counter.

Ages were calculated using an unpublished program written by J. Connelly incorporating decay constants of Jaffey et al. (1971). Analytical errors of isotope ratios, reported at two sigma, were calculated with a program modified by J. Connelly after an unpublished error propagation program written by L. Heaman (Royal Ontario Museum, Toronto, Canada). Linear regressions were calculated using the procedure of Davis (1982); an acceptable probability of fit is 10%, corresponding to an MSWD of 2.

Appendix C: Cathodoluminescence Techniques

Zircons of different morphologies were selected to characterize their origin as igneous or metamorphic. Grains were mounted in epoxy and polished to their central sections. Analyses were performed at the University of Texas at Austin on a JEOL scanning electron microscope equipped to observe cathodoluminescence, by which variations in intensity of the luminescence reveals growth patterns.
